The importance of a node (or cluster of nodes) in a network is usually determined by the number of shortest paths (or the most likely paths) it lies on. These shortest paths, however, capture only a fraction of the total network traffic. In this study, we assess the potential of some well-known centrality measures for the identification of key nodes by considering network traffic from the perspective of every path in the network, and determine the nodes that are most responsible for network traffic. The results show that the in-degree and out-degree centrality measure fail to capture the proportion of the total network traffic, which instead should be addressed using local analysis of the network's shortest paths. We compare four network centrality measures (the PageRank centrality, the degree centrality, the betweenness centrality, and the closeness centrality) and find that they agree quite well with our proposed measure, the key node potential. Nevertheless, there are clear differences, especially in the case of the pageRank distribution, for which the key node potential has a sharper cutoff for low degree nodes. The key node potential also demonstrates several useful features that can be used to efficiently find key nodes for large-scale networks.A tiny newcomer to the world of dog shows is doing great, according to a just-released test result.
